INTRODUCTION

The tennis serve is one of the fundamental strokes during the development of a match and could be a key factor determining its outcome [10]. It is also one of the most difficult strokes to execute as the act of throwing the ball and then hitting it on its downward flight, requires a complex multisegment co-ordination between the ball, the hitting body segments, the trunk and the lower limbs, [2]. It is the only hit in tennis where the player depends solely on himself (closed feedback task), and therefore the technique supposes the most important role in the shot.

As a throwing and hitting pattern, the tennis serve is a sport skill classified as an over arm pattern [22] where its main goal is to achieve an appropriate trajectory and optimal speed of the racquet at impact.

Over the last years, the speed of the tennis serve from top players has been increasing reaching 249.4 km/hr from Andy Roddick in the 2004 season, [19]. High velocities in the tennis serve guarantees more winning points, and if this successful first serve is combined with a good percentage, the probability of winning the match increases considerably [4].

Haake et al. [18], showed that when the speed of the tennis serves is over 160 km/h, the number of errors at the return increases significantly.

The ball speed of previous studies registered at tennis serves were under 30 m/s (27 and 28.83 m/s) [20,27]; while Elliott et al. [10], reported 34.4 m/s in females and 42.2 m/s in males. Normally, authors have used the speed of the tennis ball after impact as the performance criterion. The tennis serve is a based kinetic chain movement where the objective is to achieve the highest velocity of the free end.

The kinetic chain is based on the “kinetic link principle” where the generation of high end-point velocity accomplish with the use of accelerating and decelerating of adjoining links. That is, the segments reach its maximum of speed consecutively beginning for those farthest of the kinetic chain free end [22].

The Kinetic Energy (see formula in Appendix 2) is composed by a linear component which accounts with the linear velocity of a segment and by a rotational component which considers the angular velocity of the segment. There are no studies of the tennis serve

KINETIC ENERGY TRANSFER DURING THE TENNIS SERVE

AUTHORS: de Subijana C. L., Navarro E.

Sport Biomechanics Laboratory, Technical University of Madrid, Spain

ABSTRACT: Several studies have established the pattern used in the over arm hitting and throwing movements, however to date there has not been one which statistically expresses the Kinetic Link Principle of the tennis serve. The main goals of this study were: first to investigate the kinetic energy transmission pattern using a complete mechanical body model and second, to create a tool which could help evaluating the individual technique of a tennis player. This tool was a statistical procedure which expressed the individual technique of a player as a mathematical function. Fourteen and twelve flat tennis serves of two top tennis players landing in an aiming area were recorded with two synchronized video cameras at 125 Hz. The experimental technique was 3D photogrammetry. A 28 points body model with five solid-rigid (the pelvis, the thorax, the upper arms and the racquet) was built. The kinetic energies from the body segments were considered the biomechanical parameters. The mean speeds of the balls were 41.9 m/s (150.9 km/hr) and 38.1 m/s (137.2 km/hr).

A Kinetic Sequential Action Muscle principle based on the kinetic energy transfer was probed statistically by mean a correlation analysis [3]. This pattern showed the existence of a proximal to distal sequence of kinetic energy maximums. A significant (p<0.05) discriminant function for each player could predict the category of the serve (“good” or “bad”) in the 78.6% and 100% of the cases. This function facilitated the understanding of the individual technique of a tennis player showing that this could be a tool for the tennis training complementary to the qualitative (observational) analysis.

KEY WORDS: biomechanics, tennis, serve, kinetic energy
which use the kinetic energy as the main biomechanical parameter. Elliot [8], detailed a sequence of body movements occurring during the acceleration phase as follows: first the elbow extension, second the internal rotation of the upper arm with the lower arm pronation, and finally the wrist flexion occurred. The angular velocity of the upper arm internal rotation reached 2418.5°/s in males and 1348.7°/s in females.

Fleisig et al. [14], demonstrated a complete kinetic chain, taking into account the knee flexion and the trunk movements. The maximum angular velocities events order was:

- Knee extension (800 °/s).
- Trunk tilt rotation (440 °/s).
- Thorax rotation (870 °/s).
- Pelvis rotation (440 °/s).
- Elbow extension (1510 °/s).
- Wrist flexion (1950 °/s).

Upper arm internal rotation (2420°/s in males and 1370°/s in females)

It is surprising the thorax action was previous to the pelvis and also how late upper arm internal rotation occurred.

Gordon and Dapena [16], analysed the movements performed from the maximum knee flexion to impact and found that the major contributors to the head racquet speed time were: the shoulder external rotation, the wrist extension, the twist rotation of the lower trunk, the twist rotation of the upper trunk, the shoulder abduction, the elbow extension, the ulnar deviation rotation, the second twist rotation of the upper trunk and the wrist flexion.

Reid et al. [26], demonstrated that different types of tennis serves, “foot up”, “foot back” and “Arm based”, could be associated with lower limb kinematics. In fact they showed a general pattern based on discriminant analysis where the serve technique depends directly on the range of the front knee extension, the range of the rear knee extension and the peak of angular velocity of the rear knee.

None of the previous studies analysed the “kinetic link principle” in the way of how the deceleration of one segment influences the acceleration of the next one in the kinetic chain. Analysing the kinetic energy transfer from one segment to another until impact could provide greater understanding of the tennis service mechanics. In order to study the transmission of energy between segments, a mechanical model that considers the segments as solid rigid (six degrees of freedom) and that takes into account both the linear and rotational energy is required.

Coaches are frequently faced with the task of observing movement and then offering advice about the improvement of technique [3]. To be successful, this process requires a model against which a comparison can be done. Also, objective procedures of evaluating the technique are needed by the coaches in order they can give a good feedback to their athletes. Consequently, the first goal of this study was to develop a mechanical body model applied to tennis, which would take into account the energy transfer between...
the segments and the racquet. The second goal was to develop a biomechanical tool which can be applied by coaches during the technical training process. This tool will be based on the concept that the individual characteristics of the player should be taken into account as a reference during the technical training.

MATERIALS AND METHODS

3D photogrammetry was used to collect data from two female top tennis players ranked around 40 and 60 WTA that week. Player A was 1.63 m tall and had a 62.5 kg, of mass while player B was 1.61 m tall and had a 61 kg, of mass. players specifically warmed up prior data recording session. Two digital high velocity colour video cameras KODAK MOTIONCORDER Analysyr SR-500-c. with a 125 Hz. filming frequency were used. One camera recorded a side view and the second one recorded frontal angle close to the tennis net. The location of the cameras changed throughout the session as one player was right-handed and the other left-handed (Fig. 1). Both cameras were genlocked.

Fifteen flat tennis serves which landed in the aiming area from each player were registered. This aiming area was a square of 2 m length (Fig. 1) considered as the “natural” target area for first serves of both players. Each serve was recorded from the toss of the ball until the follow-through after impact. Of all the registered serves, a total of 12 from player A and 14 from player B were analyzed.

The processing phase required digitalizing points of the mechanical model in each frame and also of the points which defined the calibration object. The calibration object was a pre-calibrated cube of 2 m length which comprised the space where the movement was produced and it was recorded before filming the serves (Fig. 2). The error associated with the calibration was less than 1 mm. The DLT, Direct Linear Transformation (Abdel-Aziz, 1971) was applied to obtain the 3D coordinates.

The mechanical model was adapted from Clauser et al. [5], and Zatsiorsky et al. [31], taking a 28 point model definition into consideration (Fig. 3). Twenty three points were from the body (foot toe, ankle, heel, knee, hip, abdominal, lower sternum, sternum, gonion, vertex, shoulder, elbow, wrist and hand), 4 from the racquet (both sides at racquet head, proximal and the distal point at the racquet head), and one point for the ball.

Seventeen segments were defined: 12 as bars (5 degrees of freedom) and 5 as solid-rigids (6 degrees of freedom). Head, lower arms, hands, abdomen, thighs, legs and feet were considered as bars.

The inertial reference system followed the axis of the calibration object. The X axis was from back to front, the Y axis, from right to left and the Z axis was vertical. In order to obtain the 6 degrees of freedom from the solid-rigids, fixed Local Reference System (LOC) in accordance with the anatomic axis, were determined (Figs. 1-3). Local Reference Systems were defined from the coordinates (x,y,z) of three non-linear point coordinates in the segments pelvis, the thorax and the racquet. Three points at the shoulder, elbow and wrist taking the elbow as a joint of one degree of freedom [25] were used to define the upper arms LOCs (Fig. 3) (see Appendix 1).

The inertial parameters of the human body were taken from De Leva [7] after measuring the weight and height of both players. The racquets were “Fischer Pro One” y “Volk Classic 7 Pro”, with dimensions, mass and “swing weight” known. The moment of inertia of the racquet about its medial-lateral axis was calculated applying the parallel axis theorem and published racquet “swing weight” data, [28]. The moment of inertia about the vertical axis was found following Brody’s (1985) specifications where the moment of inertia (kg·m^2) = mass (kg) head width^2 (m^2)/ 17.75. The moment of inertia about the anterior-posterior axis was the sum of the two other principals moments of inertia.

The filtering and interpolation was done through 5th order spline functions [29]. The method developed by Craven and Wahba (1979) introduced by Woltring [30], was used for calculating the smoothing factor. This procedure takes into account the “real mean error” being this error estimated from the digitization error. It was obtained from digitalizing 3 non-consecutive frames 30 times. The resulting mean error at the coordinates of a point was established at 0.015 m similar to Fleisig et al. [14], which obtained 0.014 m.
Hitting pattern parameters. The Ball Speed (Vb) and the Body Segments’ Kinetic Energies (Ke) were the parameters chosen for this study. The Ball Speed was measured at the instant after impact, when the ball left the racquet strings. The 3D coordinates of the ball were not filtered nor smoothed as Gordon and Dapena [16], suggested. The Kinetic Energy was taken as the sum of the Translation Kinetic Energy and the Rotation Kinetic Energy (see Appendix 2).

Statistical parameters. Normalized Parameters were defined for the statistical study. The normalized parameters expressed the increments (positive or negative) in each interval, normalized with respect to the initial kinetic energy (see Appendix 3).

Different groups of body segment kinetic energies were considered in each player. The definition of the body segment groups were based on the sequences of movements produced by each player. In a first qualitative analysis, as Knudson [21], recommended, the players showed very different techniques. Player A had an abbreviated swing with a “foot back” technique, while player B used a full swing with a “foot up” technique. In player A both feet were maintained separate throughout the shot. At Player B the feet started separate but they gather together at the same time as knee flexion occurred. It could be seeing that player A rotated less in general than player B.

For player A, the body segment kinetic energy groups made were Lower Limbs (LL Ke), Trunk (Tr Ke), Upper arm (Ua Ke), Lower arm (La Ke), and Hand & Racquet (HR Ke). In the case of player B, the increasing of normalized kinetic energy was applied to these body segment groups: Lower limbs and pelvis (LL-pel Ke), thorax and upper arm (Th-ua Ke), Lower arm (La Ke) and Hand & Racquet (HR Ke).

The whole serve was divided into 4 intervals defined by the group of body segments. Kinetic energy peaks. The events which determined each interval were: t1, maximum knee flexion with both feet on the ground, t2, maximum Tr Ke for player A and maximum LL-pel Ke for player B, t3 maximum Ua Ke for player A and maximum Th-ua Ke for player B, t4, maximum La Ke and t5, maximum HR Ke.

At first, it was estimated the Maximum External Rotation (MER) as a key event but after analysing the maximum kinetic energy of the upper arms, (Max Ke u-arm), the event did not take place in both players before the max Ke u-arm. In player A, MER was, (mean ± SD), at -0.075±0.009 s before impact and maximum Ke u-arm was at -0.106±0.006 s. At player B MER was -0.116±0.005 s and maximum Ke u-arm was 0.098±0.006 s. This meant that for player A the MER followed the maximum kinetic energy at upper arm because the external rotation was negligible. At Player B happened in a more logical sequence with first MER followed by the max Ke u-arm. This fact supported the idea that the individual technique has to be taken into account in the performance evaluation.

A correlation analysis between the parameters in each interval was carried out for both players in order to establish the existence of a kinetic energy transfer model. A discriminant analysis determined the hitting pattern of each player.

![Kinetic Energy from a Player](image-url)
**RESULTS**

Performance criteria and established levels. Player A reached a mean speed of the ball of 41.9±1.6 m/s, (150.9 km/h), while player B achieved 38.1±1.2 m/s, (137.2 km/h). The studies from Fleisig et al. [14], and Elliott et al. [9], which measured the mean speed of the ball by radar of the 3 best serve from the female tennis players at the 2000 Sydney Olympic Games, was 149.3 km/h. This ratified the level of the sample; both players were top tennis players.

The ball speed was the performance criteria established to classify the serves. The speed was estimated as the mean velocity between the last frame where the ball was in contact with the racquet strings and the next frame. (1/125 s after impact).

The performance levels of the player’s serves were established as level 1 being “good” serves and level 2, “bad” serves. The median of the ball speed measured was used to classify the serves. For player A the median was 41.4 m/s and for player B the median was 38.1 m/s. The significant differences of level 1 and level 2 of the tennis serves were at p<0.05 for player A and at p<0.01 for player B.

Kinetic Chain. The evolutions of the kinetic energy throughout the shot in both players from the maximum knee flexion until some frames after impact are shown in Figures. 4 and 5.

Player A, at the initial interval (t1-t2), started the increment of lower arm kinetic energy along with the hand and racquet, and upper arm. The trunk reached its maximum energy while the lower limbs decreased. At the t2-t3 interval, the lower limbs continued decreasing; the trunk also decreased, while the upper arm, the lower arm and the hand and racquet energy increased their energies. At the t3-t4 interval, the lower arm reached its maximum energy, while the hand and racquet increased their energy. The upper arm energy decreased at the same time as the lower limbs and the trunk. In the last interval, the hand and racquet reached its maximum values, considerably higher than the other parameters. The lower arm, the upper arm and the trunk decreased their energy while the lower limbs increased slightly as a consequence of their movements during the follow-through.

For player B during the first interval t1-t2, the lower limbs and pelvis reached their maximum energy, followed by increases on thorax and upper arm, and the hand and racquet energy. At t2-t3, the hand and racquet kept increasing, the thorax and upper arm reached its maximum, and the lower limbs and pelvis began to decrease its energy. At t3-t4, the lower arm reached its maximum energy with the hand and racquet increasing, while the lower limbs and thorax and upper arm decreased their energy. At the t4-t5 interval, the hand and racquet group reached energy values significantly higher in comparison to the other body segment groups. During this interval, the thorax and upper arm and the lower arm lost energy.

The correlation analyses of the parameters are shown in Tables 1 and 2. The significant correlations found in each interval, which divided the shot, are shown in both tables. The significant correlation found indicated a possible relationship between the increase and decrease of the body segment group energies during an interval.

For player A during t1-t2, all the correlations between the parameters which increased were positive (all at p<0.05 but p<0.01 at the upper arm with the lower arm). At t2-t3, there were positive correlations between the decrease of the lower limbs and the trunk, (p<0.05), and between the increase of the upper arm and the lower arm (p<0.01). The negative correlations between the lower limbs decrease and the upper arm increase (p<0.05), and between the trunk and the lower arm (p<0.05), indicated a possible energy transfer relationship between the deceleration at the thighs and trunk, and the acceleration at the upper arm and lower arm. During the t3-t4 interval, the trunk decrease was negatively correlated with the lower arm increase (p<0.05). In the last interval, t4-t5, the lower limbs increase was negatively correlated with the lower arm decrease (p<0.01). On the other hand, the trunk and upper arm decrease were positively correlated (p<0.05).

For player B, during the t1-t2 interval, all the parameters increased. The thorax and upper arm and the hand and racquet increases were positively correlated (p<0.01). At t2-t3, the increase of the thorax and upper arm and the increase of the lower arm, were negatively correlated (p<0.01) with the lower limbs decrease. This could explain the energy transfer from the lower limbs to the upper lower arm segments. However, the thorax and upper arm and lower arm increase were positively correlated (p<0.05). At t3-t4, all parameters were correlated, with a positive correlation between the lower arm and hand and racquet increases (p<0.01), and between the lower limbs and thorax and upper arm decreases (p<0.01). Negative correlation between the increasing parameters; lower arm (p<0.01) and hand and racquet (p<0.05 y p<0.01), with those which decrease, the lower limbs and upper arm energies was identified. This could suggest an energy transfer. In the last interval, the thorax and upper arm energy decreases were positively correlated (p<0.05), and the hand and racquet and lower limbs increases were correlated negatively (p<0.01).

Hitting pattern. A discriminant analysis of the dependent parameters (body segment groups of normalized energies) was carried out to obtain a mathematical expression which would explain the individual hitting pattern of each player. Once the two performance levels were established, (“good” and “bad”), a discriminant function which establishes a linear combination between the dependent parameters.
Kinetic energy transfer during the tennis serve

while also allowing speculations about to be made on individual pattern of movements.

The discriminant function is positive, above 0, when the serves are from the Group 1 ("good"), and is negative, below 0, when the serves are from Group 2 ("bad"). It expresses the values which the parameters should reach taking care of the coefficient value and the sign of the parameters.

Player A discriminant function:

\[
F(d) = -0.492 \cdot (2.3 \text{ Tr Ke}) + 0.006 \cdot (2.3 \text{ UA Ke}) + 0.269 \cdot (3.4 \text{ Tr Ke}) - 0.25 \cdot (2.4 \text{ La Ke}) + 0.483 \cdot (4.5 \text{ Tr Ke}) - 0.474 \cdot (4.5 \text{ UA Ke}) - 0.071. 
\]

Canonic Correlation: 0.934
Statistical significance: p<0.05

Player B discriminant function:

\[
F(d) = 0.003 \cdot (2.4 \text{ La Ke}) - 0.103(2.3 \text{ Th-ua Ke}) + 0.176 \cdot (4.5La Ke) + 0.66 \cdot (3.4LL-pel Ke) + 4.855. 
\]

Canonic Correlation: 0.789
Statistical significance: p<0.05
78.6 % of the cases Predicted

**DISCUSSION**

There are several studies on over hand throwing and hitting which have identified a movement pattern based on a sequence of body segment movements beginning with those far from the hitting segment and followed by the ones closer to it. In baseball pitching Escamilla et al. [13], and Fleisig et al. [15], in American Football; in general throwing skills Dapena and McDonald [6], Grande [17], Mero et al. [21] and Morris et al. [24].

The Kinetic Link Principle (Kreighbaum & Barthels, 1981) found was based on a sequence of maximum kinetic energies from proximal to distal segments. There was no energy transmission at player A in the interval t1-t2. In t2-t3 the energy decrease at the lower limbs and trunk are related to the increase of the upper arm and lower arm energies. During t3-t4, the decrease of energy at the trunk was correlated with the energy increase at the upper arm and lower arm, once again. At t4-t5, there is a possible relationship between the energy loss of the lower limbs and the increase of the lower arm.

Similarly there was no energy transmission at Player B in t1-t2 interval. During t2-t3 the energy losses of the lower limbs were connected to the increase of energy of the lower arm and thorax. At t3-t4 there were strong relationships between the decrease of energy of the lower limbs and thorax and upper arm, and the increase of the distal segments as the lower arm and hand and racquet. Finally during t4-t5, the deceleration of the lower limbs appeared to be related to the increase of energy of the hand and racquet.

The angular velocities recorded are shown in Table 3 (Player B) has negative values because she rotates in the opposite direction than player A through the Z axis). The pelvis and thorax rotation about the vertical axis measured by Fleisig et al. [14], reached 440º/s and 870º/s, respectively. In this study, player A achieved 197º/s (Pelvis) and 405º/s (Thorax), and player B 416º/s and 618º/s. Upper arm internal rotation was studied by Elliott et al. [12], and registered 2090 º/s for amateur players and by Fleisig et al. [14], who registered 2040º/s male and 1370º/s female tournament players. In this study player A upper arm internal rotation was 1962º/s and player B 1404º/s. While the players of this study obtained discrete values at the pelvis and thorax rotation, the upper arm internal rotation were both similar to results from Fleisig et al. [14]. Table 4 shows the key events sequence. Both coincided with Fleisig et al. [14]. The upper arm maximal internal rotation occurred as the last event, and the thorax rotation was previous to the pelvis rotation.

We find relevant the fact that the sequence of angular velocities at the thorax, pelvis and upper arm found in this study and the previous studies do not show the sequence of maximum kinetic energies found from pelvis, thorax, upper arm, lower arm and finally at the hand and racquet segment. This could confirm the existence of a kinematic pattern different to the dynamic pattern. It is important to point out that in the kinetic energy; the rotation and translation movement are taken into consideration.

The individual technique pattern obtained by player A based on the discriminant function found, was more stable than that of player B. The equation reveals that during t2-t3 the player based her technique on a strong decrease of the trunk energy and high increase of the upper arm energy. The t4-t5 decrease of energy at the lower arm is higher in those serve which were classified as “good”. Analysing the discriminant function from player B, The following events should occur: a moderate increase of energy of the thorax and upper arm at t2-t3, a moderate decrease of energy at the lower limbs at t3-t4 and at t4-t5 in the lower arm’s energy. Finally, in opposition the increase of energy of the lower arm from t2 to t5 should be as higher as possible.

As Reid et al. [26], established, both players’ technique depend on parameters related with the lower limb kinematics.

**CONCLUSIONS**

There are no previous studies which have analysed the kinetic energy of the tennis serve which may be use for comparison. A model of energy transfer has been established for both players with the existing correlation throughout the intervals of the shot. With the discriminant functions recognised, the individual technique pattern of the shot has also been identified.

The lower limbs movements, principally the ankles and knees, were fundamental at the time to execute the best serves. This fact
was previewed at the first qualitative analysis and it was confirmed with the discriminant analysis. Therefore, any biomechanical study of a tennis shot, should consider all body segment movements. Player A obtained a higher ball speed in comparison to player B. Her hitting pattern showed that this player’s technique was based on the energy transmission between body segments, particularly the trunk decrease of energy and the increase of the upper arm energy during t2-t3. Player B’s hitting pattern showed that good serves were based on a maximum acceleration of the lower arm from t2 to t4 and a good control of the lower limbs flexion and extension. Player A had a more linear “style”, while player B used more rotations in her technique.

Many coaches tend to apply –reproduce- a universal pattern to their player. However, some authors support the idea that individual technical pattern should be carefully considered by coaches during the training process. A method has been developed which allows individual technique to be identify. This method has several advantages. The most important one is that the individual technique can be obtained without interfering the players’ movement (external validity). Today it is possible to integrate a court in the biomechanics lab recording the movement at real time with a 3D Capture System (i.e. Ariel, Vicon, SIMI); that is, to create a virtual match situation where the player can perform the movements while the biomechanical parameters are being determined with a high external validity. In a short term period after the biomechanical training session (no more than a week) a complete report could be given to the coach [11].

APPENDIX

1. FIXED LOCAL REFERENCE SYSTEM IN SOLID RIGID
At the upper arms, (the elbow joint considering it as one degree-of-freedom):
\[
P_1 = \text{Position vector at the shoulder joint.}
\]
\[
P_2 = \text{Position vector at the elbow joint}
\]
\[
P_3 = \text{Position vector at the wrist joint}
\]
The unit vectors of the fixed local reference system at the mass centre of the upper-arm segment are calculated:
\[
\hat{\vec{k}} = \frac{P_2 - P_1}{||P_2 - P_1||}
\]
\[
\hat{i} = \frac{[P_2 - P_1] \times [P_3 - P_1]}{||[P_2 - P_1] \times [P_3 - P_1]||}
\]
\[
\hat{j} = \hat{k} \times \hat{i}
\]

2. KINETIC ENERGY
The Kinetic energy is calculated following this formula when the segment is a solid-rigid:
\[
Ec = \frac{1}{2} ml^2 + \frac{1}{2} (I_x, w_t^2 + I_y, w_t^2 + I_z, w_t^2)
\]
And When the segment is a bar the calculation follows this equation:
\[
Ec = \frac{1}{2} m \hat{v}^2 + \frac{1}{2} (I_{\hat{x}} \hat{w} \hat{z}^2)
\]
The axis \(\hat{\vec{i}}\) is an orthogonal axis at the bar neither \(\hat{\vec{j}}\) nor \(\hat{\vec{k}}\). At its moment of inertia is estimated to be the mean of the moment of inertia at those axis.

3. NORMALISED KINETIC ENERGY
For example the Lower Limbs Kinetic energy increase from t1 to t2: (\(\triangle LL Ke 12n\)) is calculated following these steps:
\[
\text{LL Ke} = \text{KE Left Thigh} + \text{KE Right Thigh} + \text{KE Left Tibia} + \text{KE Right Tibia} + \text{KE Left Foot} + \text{KE Left Foot} + \text{Ke Pel}
\]
\[
\triangle LL KE12 = \text{LL Ke 2} - \text{LL Ke 1}
\]
\[
\triangle LL Ke 12n = \triangle LL KE12 / \text{LL Ke 1x 100}
\]
